ACG Clinical Guideline: Liver Disease and Pregnancy

Tram T. Tran, MD, FACG, FAASLD¹, Joseph Ahn, MD, MS, FACG² and Nancy S. Reau, MD, FAASLD, FAGA³

Consultation for liver disease in pregnant women is a common and oftentimes vexing clinical consultation for the gastroenterologist. The challenge lies in the need to consider the safety of both the expectant mother and the unborn fetus in the clinical management decisions. This practice guideline provides an evidence-based approach to common diagnostic and treatment challenges of liver disease in pregnant women.

Am J Gastroenterol advance online publication, 2 February 2016; doi: 10.1038/ajg.2015.430

Management of pregnant women with liver disease is a common clinical scenario, and one that can be challenging given the need to consider not only the expectant mother, but also the unborn fetus in treatment decisions. The purpose of this guideline is to provide a review of the diagnostic and treatment challenges of managing liver disease in pregnant women. The evidence behind approaches to diagnosis and treatment of liver disease in pregnant women are assessed to provide management recommendations.

These recommendations are based on the following: (i) a search and review with analysis of the recently published world literature on the topic using Medline search from 1946 to present, EMBASE 1988 to present, and SCOPUS from 1980 to present using the search terms listed in the Appendix. (ii) Guideline policies of the ACG. Intended for use by physicians and allied health professionals, these recommendations suggest preferred approaches to the diagnostic, therapeutic, and preventive aspects of care. These are intended to be flexible and adjustable for individual patients (1).

To best characterize the evidence cited in support of the recommendations, the ACG practice guidelines have implemented the use of the Grading of Recommendation Assessment, Development, and Evaluation (GRADE) system. The strength of recommendations in the GRADE system is classified as strong (when the positive effects of an intervention or recommendation clearly are greater than the negative effects) or conditional (when there is uncertainty regarding the positive vs. negative aspects of the recommendation) (2). The quality of evidence supporting strong or conditional recommendations is designated by one of four levels: high (suggesting that further research is unlikely to change the authors’ confidence in the estimate of effect), moderate (further research would be anticipated to have an impact on the confidence in the estimate of effect), low quality (further research would be anticipated to have an important impact on the confidence in the estimate of effect and also likely change the estimate), or very low quality (the estimate of effect is uncertain) (2).

To determine the level of evidence, the results from the selected papers with the greatest level of evidence were extrapolated and utilized in the GRADE program (http://www.gradepro.org). A summary of the recommendations are outlined in Table 1.

EVALUATION OF THE PREGNANT PATIENT WITH ABNORMAL LIVER ENZYMES

Recommendations:

1. A pregnant patient presenting with abnormal liver tests should undergo standard workup as with any non-pregnant individual (strong recommendation, very low level of evidence).

The basis for the workup of abnormal liver tests in a pregnant woman should be predicated on understanding the normal physiological changes observed during pregnancy.

The incidence of abnormal liver tests in pregnant women is ~3–5%, even in this relatively young and healthy population. Some liver test results, which would otherwise suggest liver or biliary dysfunction in the non-pregnant individual may in fact be “normal” in the pregnant woman. Conversely, abnormal test results should be appropriately evaluated as some diseases newly diagnosed in pregnancy may require more immediate intervention for the mother or the neonate (e.g., herpes hepatitis, hepatitis B; Table 2) Generally, the majority of liver tests remain in the normal range in pregnancy except those produced by the placenta (alkaline phosphatase, alphafetoprotein) or impacted as a result of hemodilution (albumin, hemoglobin). Of note, during pregnancy, cardiac output is increased by 40–45% with substantive increases to the renal, uterine, and skin systems. However, the liver blood flow shows little change during pregnancy, suggesting a relative decrease of total percent of cardiac output (3). Any abnormality seen in transaminases and bilirubin needs further evaluation (Figure 1).

Table 1. Recommendation statements

| Initial evaluation of pregnant patient |
| A pregnant patient presenting with abnormal liver tests should undergo standard workup as with any non-pregnant individual (strong recommendation, very low level of evidence). |

| Imaging in pregnancy |
| Ultrasound is safe and the preferred imaging modality used in assessment of abnormal liver tests suggestive of biliary tract disease (strong recommendation, low level of evidence). |
| Magnetic resonance imaging without gadolinium can be used in the second and third trimester (conditional recommendation, low level of evidence). |
| Computed tomography scans carry a risk of teratogenesis and childhood hematologic malignancies but may be used judiciously with minimized radiation protocols (2–5 rads; conditional recommendation, very low level of evidence). |

| Endoscopy in pregnancy |
| Endoscopy is safe in pregnancy but should be deferred until the second trimester if possible (strong recommendation, low level of evidence). |
| Meperidine and propofol can be used for endoscopic sedation (strong recommendation, moderate level of evidence). |

| Management of biliary disease in pregnancy |
| ERCP can be performed when indicated for pregnant women presenting with biliary disease that strongly necessitates intervention such as biliary pancreatitis, symptomatic cholangitis, and/or cholangitis. Minimizing fetal exposure to fluoroscopy is imperative (strong recommendation, low level of evidence). |
| Symptomatic cholecystitis should be managed with early surgical intervention with laparoscopic cholecystectomy (strong recommendation, low level of evidence). |

| Liver masses in pregnancy |
| Asymptomatic hemangioma and focal nodular hyperplasia do not need routine imaging or surveillance during pregnancy (strong recommendation, very low level evidence). |
| Hepatic adenomas should be monitored with ultrasound during pregnancy for growth. Patients with large adenomas (>5 cm) should be referred for resection prior to pregnancy (strong recommendation, low level of evidence). |

| Hepatitis B in pregnancy |
| Active–passive immunoprophylaxis with hepatitis B immunoglobulin and the HBV vaccination series should be administered to all infants born to HBV-infected mothers to prevent perinatal transmission (strong recommendation, low level of evidence). |
| Women chronically infected with HBV and high viral load (>10⁷ log copies/ml [200,000 IU/ml] and higher) should be offered antiviral medication with tenofovir or telbivudine in the third trimester to reduce perinatal transmission of HBV (strong recommendation, low level of evidence). |
| C-section should not be performed electively in HBV-positive mothers to prevent fetal infection (strong recommendation, very low level of evidence). |
| Women chronically infected with HBV should be allowed to breastfeed as recommended for infant health (strong recommendation, very low level of evidence). |

| Hepatitis C in pregnancy |
| All pregnant women with risk factors for HCV should be screened with anti-HCV antibody. Screening should not be performed in women without risk factors for HCV acquisition (strong recommendation, low level of evidence). |
| Invasive procedures (e.g., amniocentesis, invasive fetal monitoring) should be minimized in infected mothers and their fetus to prevent vertical transmission of hepatitis C (strong recommendation, very low level of evidence). |
| C-section should not be performed electively in HCV-positive mothers to prevent fetal infection (strong recommendation, very low level of evidence). |
| Women chronically infected with HCV should be allowed to breastfeed as indicated for infant health (strong recommendation, very low level of evidence). |
| Hepatitis C therapy should not be offered to pregnant women to either treat HCV or decrease the risk for vertical transmission (strong recommendation, very low level of evidence). |

| Liver disease unique to pregnancy |
| The treatment of hyperemesis gravidarum is supportive and may require hospitalization (strong recommendation, very low level of evidence). |

| Intrahepatic cholestasis of pregnancy |
| Owing to increased risk of fetal complications with IHCP, early delivery at 37 weeks is recommended (strong recommendation, very low level of evidence). |
| Ursodeoxycholic acid, should be given at 10–15 mg/kg, to women with IHCP for symptomatic improvement (strong recommendation, moderate level of evidence). |

| Preeclampsia and eclampsia |
| Preeclampsia with hepatic involvement elevates the diagnosis to severe preeclampsia. After 36 weeks, women with severe preeclampsia should be delivered promptly to limit maternal and fetal complications (strong recommendation, very low level of evidence). |

| HELLP syndrome |
| HELLP syndrome should be managed by prompt delivery, especially after 34 weeks gestation (strong recommendation, very low level of evidence). |

Table 1 continued on following page
The first step in assessing a woman presenting at any stage of pregnancy with abnormal liver tests should be the same as with any non-pregnant patient. A complete history, physical exam, and standard serological workup should be performed as indicated by the clinical presentation. Initial evaluation of these patients can be categorized into two general groups: (i) pre-existing and coincidental, not related to pregnancy, or (ii) related to the pregnancy itself.

**IMAGING**

**Recommendations:**

2. Ultrasound is safe and the preferred imaging modality used in assessment of abnormal liver tests suggestive of biliary tract disease (strong recommendation, low level of evidence).

3. Magnetic resonance imaging (MRI) without gadolinium can be used in the second and third trimester (conditional recommendation, low level of evidence).

4. Computed tomography (CT) scans carry a risk of teratogenesis and childhood hematologic malignancies but may be used judiciously with minimized radiation protocols (2–5 rads) (conditional recommendation, very low level of evidence).

---

Table 1. Continued

| Platelet transfusion to 40,000–50,000 cells/μl should be considered before delivery, especially if cesarean section is likely (conditional recommendation, very low level of evidence). |

It may be clinically appropriate and necessary during pregnancy to image the liver, hepatic vasculature, or biliary system. Any pregnant woman presenting with abnormal aminotransferases or jaundice should first undergo an abdominal ultrasound. Ultrasound, with or without Doppler imaging, as it uses sound waves and not ionizing radiation, has never been shown to have any adverse fetal effects (4,5). Therefore, there are no contraindications to ultrasound in pregnancy and it should be used as the imaging modality of choice.

Teratogenicity has been clearly established, with large doses of radiation >100 rad, linked in humans to growth restriction and microcephaly, among other adverse effects. The greatest exposure risk is at 8–15 weeks of gestation. Fetal risks of anomalies and growth restriction appear not to be increased if the exposure is <5 rad. Fetal exposure for commonly used gastrointestinal imaging ranges from 100 mrad, for a single abdominal film, to 2–4 rad, for a barium enema or small bowel series, to 3.5 rad for a CT scan of the abdomen (6,7). If ultrasonography is indeterminate and further imaging is necessary, judicious use of CT or MRI without gadolinium may be considered for the expeditious diagnosis of an acute presentation. Oral and intravascular contrast agents used for CT contain derivatives of iodine which do not appear teratogenic in animal studies. However, neonatal hypothyroidism has been associated with iodinated contrast agent exposure during pregnancy (8). Gadolinium is not recommended as it crosses the placenta and is excreted by the fetal kidneys into the amniotic fluid where it can remain for long periods, exposing the fetal pulmonary and gastrointestinal systems to potential injury. Animal studies have also reported spontaneous abortion, skeletal abnormalities, and visceral abnormalities with high doses of gadolinium (4).

Fortunately, the necessity of liver biopsy for diagnosis of disease in pregnancy is uncommon as most etiologies can be determined in this population by biochemical, serological, and clinical parameters. However, if required, percutaneous liver biopsy can be performed safely. Transjugular liver biopsy can also be performed but carries some limited radiation exposure of 0.05–0.1 rad (9,10).

**SAFETY OF ENDOSCOPY IN PREGNANCY**

**Recommendations:**

5. Endoscopy is safe in pregnancy but should be deferred until the second trimester if possible (strong recommendation, low level of evidence).

6. Meperidine and propofol can be used for endoscopic sedation (strong recommendation, moderate level of evidence).

Although clinical studies on the safety and effectiveness of endoscopy for the pregnant patient have been limited, endoscopy can be safe and effective if careful assessment of the risks, benefits, and clinical rationale is performed. One of the most important critical issues in endoscopy of the pregnant patient is to ensure hemodynamic stability and oxygenation. Overdation, resulting in hypotension or hypoxia, or positioning that compresses the inferior vena cava can lead to decreased uterine blood flow and fetal hypoxia. Thus, the patient should be positioned in the left lateral position to avoid vascular compression and aggressively managed with respect to intravenous hydration (11). Other concerns include teratogenicity of medications and radiation exposure.

There are currently no FDA pregnancy category A medications available for the management of sedation during endoscopy. The benzodiazepine class of sedatives (FDA category D) should be avoided in pregnancy owing to known congenital malformations (12,13). One of the most commonly used sedation medications during pregnancy is meperidine, an opiate analgesic, which has more recently been replaced by shorter acting agents, such as propofol, with lower risk for respiratory depression and seizures. Meperidine crosses the placenta and is converted to a long-lasting normeperidine, so repeated or prolonged meperidine administration should be avoided late in pregnancy or at term, as meperidine is an FDA pregnancy category C (14,15).

Propofol is an FDA pregnancy category B anesthetic which is very short acting with a rapid recovery period, which is of significant benefit in the case of a pregnant patient. If propofol is used, an anesthesiologist should monitor respiratory function closely.

Multidisciplinary consultation with obstetrics is essential, and further anesthesia and surgical opinion may be helpful in approaching endoscopy. Deferring endoscopy until the second trimester is recommended when possible and special considerations for maternal–fetal monitoring, and aspiration precautions should be undertaken.
**Liver Disease and Pregnancy**

**MANAGEMENT OF BILIARY DISEASE IN PREGNANCY**

**Recommendations:**

7. ERCP can be performed when indicated for pregnant women presenting with biliary disease that strongly necessitates intervention such as biliary pancreatitis, symptomatic choledocholithiasis, and/or cholangitis. Minimizing fetal exposure to fluoroscopy is imperative (strong recommendation, low level of evidence).

8. Symptomatic cholecystitis should be managed with early surgical intervention with laparoscopic cholecystectomy (strong recommendation, low level of evidence).

Cholelithiasis is common in pregnancy owing to the increased estrogen levels, causing cholesterol supersaturation and increased gallstone formation. Cholecystitis is the second most common surgical condition in pregnancy and occurs in ~1 in 1,600 to 1 in 10,000 pregnancies. The incidence of cholelithiasis in pregnant women is 3.5% (10). In the setting of laboratory testing indicating a possible biliary etiology, the first step in diagnosis should be an abdominal ultrasound, which has 95% sensitivity for the diagnosis of gallstones. Biliary pancreatitis, symptomatic choledocholithiasis, and cholangitis may have poor fetal outcomes without intervention. ERCP safety has been reported in multiple series, with some reports of increased pancreatitis risk (16%). Reducing fetal exposure to radiation should be attempted by limiting fluoroscopy time, external fetal shielding, and adjusting the patient position (16–20).

Symptomatic cholecystitis had been previously managed conservatively, but more recent data suggests high rates of recurrent symptoms (40–90%), increased rates of hospitalizations, preterm labor and deliveries, and spontaneous abortions when intervention is deferred. The development of gallstone pancreatitis portends a high rate (10–60%) of fetal demise. Thus, early surgical intervention with laparoscopic cholecystectomy after ERCP is preferred (21,22). One recent study of 9,714 women who underwent cholecystectomy while pregnant, reported longer length of stay than non-pregnant women and maternal and fetal complication rates of 4.3% and 5.8%, respectively (23).

**LIVER DISEASES UNIQUE TO PREGNANCY**

**Recommendations:**

11. The treatment of hyperemesis gravidarum (HG) is supportive and may require hospitalization (strong recommendation, very low level of evidence).

12. Because of increased risk of fetal complications with intrahepatic cholestasis of pregnancy (IHCP), early delivery at 37 weeks is recommended (strong recommendation, very low level of evidence).

13. Ursodeoxycholic acid (UDCA) should be given at 10–15 mg/kg to women with IHCP for symptomatic improvement (strong recommendation, moderate level of evidence).

14. Preeclampsia with hepatic involvement elevates the diagnosis to severe preeclampsia. After 36 weeks, women with severe preeclampsia should be delivered promptly to limit maternal and fetal complications (strong recommendation, very low level of evidence).

15. Hemolysis, elevated liver enzymes, and low platelets (HELLP) syndrome should be managed by prompt delivery, especially after 34 weeks gestation (strong recommendation, very low level of evidence).

16. Platelet transfusion to 40,000–50,000 cells/μl should be considered before delivery, especially if cesarean section is likely (conditional recommendation, very low level of evidence).

17. Women with acute fatty liver disease of pregnancy (AFLP) should be delivered promptly; expectant management is not appropriate (strong recommendation, very low level of evidence).

18. All women with AFLP and their children should have molecular testing for long-chain 3-hydroxyacyl-CoA dehydrogenase (LCHAD); conditional recommendation, moderate level of evidence).

19. The offspring of mothers affected by AFLP should be monitored carefully for manifestations of deficiency of LCHAD including hypoketotic hypoglycemia and fatty liver (conditional recommendation, very low level of evidence).

**LIVER MASSES IN PREGNANCY**

**Recommendations:**

9. Asymptomatic hemangioma and focal nodular hyperplasia do not need routine imaging or surveillance during pregnancy (strong recommendation, very low level evidence).

10. Hepatic adenomas should be monitored with ultrasound during pregnancy for growth. Patients with large adenomas (>5 cm) should be referred for resection before pregnancy (strong recommendation, low level of evidence).

Fortunately, liver masses discovered during pregnancy are rare and most commonly are benign. Hemangiomas, focal nodular hyperplasia, and hepatic adenoma may be discovered on routine imaging with ultrasound. Further characterization with MRI or tagged RBC scan may be needed. Patients presenting with large hemangiomas can present asymptomatically or with pain and abdominal distension. Spontaneous rupture of hemangiomas is exceedingly rare, even with large lesions, thus routine symptomatic follow-up and standard vaginal delivery is safe. Focal nodular hyperplasia is found in 3% of the population, and multiple case series in pregnant women reported routine pregnancies with good clinical outcomes. Hepatic adenomas have a higher risk of growth during pregnancy owing to hormonal stimulation, and ultrasound monitoring should be done during pregnancy. If a diagnosis of large hepatic adenoma is made in a young woman of child-bearing age, appropriate consultation and follow-up should be performed. If a hepatic adenoma is larger than 5 cm or rapid growth is noted, surgical or radiological intervention should be recommended before pregnancy. The ACG Clinical Guideline on the diagnosis and management of focal liver lesions further details this topic (24–27).
Several liver injuries are unique to pregnancy and typically resolve with delivery. Accurate identification of the insult and the potential impact on both maternal and fetal health is imperative. The gestational age of the pregnancy is an important diagnostic clue and can help tailor the diagnostic evaluation, as these insults typically occur only at certain stages of development (see Table 3).

A thorough history, including prior pregnancies, high-risk behaviors and medications, and careful physical examination is essential (28).

First trimester

**Hyperemesis gravidarum.** HG is defined by persistent vomiting, associated with loss of 5% or more of pre-pregnancy body weight, dehydration, and ketosis. HG is uncommon (0.3–2% of pregnancies), occurs early in the first trimester, and typically resolves by 20 weeks gestation. Risk factors for HG include molar pregnancy, multiple pregnancies, trophoblastic disease, prior HG, and fetal abnormalities (triploidy, trisomy 21, and hydrops fetalis) (29). Liver test abnormalities are common in HG and resolve when the vomiting stops. In all, 50–60% of hospitalized women with HG will have a mild elevation in aminotransferase levels, although AST and ALT levels more than 20 times the upper limit of normal rarely have been reported (30). Jaundice and hepatic synthetic dysfunction are uncommon. Although women with HG have increased rates of low birth weight (LBW) babies, small for gestational age babies, preterm birth, and poor 5-min Apgar scores (31), outcomes are generally favorable (32,33). Management of HG is supportive, however, given the risk for electrolyte abnormalities and dehydration, hospitalization is not infrequent (34,35).

AFLP, acute fatty liver disease of pregnancy; HELLP, hemolysis, elevated liver enzymes, low platelets; HG, hyperemesis gravidarum; IHCP, intrahepatic cholestasis of pregnancy.

In IHCP, bile acid concentrations are typically >10 μmol/l with increased cholic acid levels and decreased chenodeoxycholic acid levels. Increased bile acid concentration (>40 μmol/l) is one factor that can identify higher risk, and may be the only biochemical abnormality present. Bile acid levels also correlate with fetal distress. Most complications occur when bile acid levels exceed 40 μmol/l (41). Aminotransferase levels may also be elevated, reaching values >1,000 U/l. Ultrasonography should be performed to exclude cholelithiasis.

Maternal outcomes are excellent, however, there is a risk of fetal distress, preterm labor, prematurity, and intrauterine death (41–45). Early delivery at 37 weeks is encouraged, because intrauterine death is more common in the last month of pregnancy and few deaths occur before 37 weeks (46).

First-line therapy for IHCP is UDCA at 10–15 mg/kg maternal body weight. It is well-tolerated and safe for both the mother and fetus. UDCA increases expression of bile salt export pumps and increases placental bile transporters. UDCA therapy normalized serum bile acid patterns in babies with minimal accumulation in amniotic fluid and cord blood (47). A recent meta-analysis also found that women who received UDCA had better outcomes with less pruritus, improved liver enzymes, and possibly improved fetal outcomes (48). UDCA is more effective than cholestyramine or dexamethasone in controlling pruritus. Dexamethasone may be used, if needed, to promote fetal lung maturity before delivery, as there is a higher rate of prematurity in IHCP.
**Preeclampsia and eclampsia.** Preeclampsia is characterized by new onset hypertension (systolic blood pressure ≥140 mm Hg or diastolic blood pressure ≥90 mm Hg) and proteinuria (≥300 mg/24 h) after 20 weeks of gestation (49,50). Organ dysfunction defines severe preeclampsia and can include hepatomegaly and hepatocellular injury. Up to 7.5% of all pregnancies are affected, but only 25% of preeclampsia cases are severe. Liver involvement is not a common expression and when it does occur symptoms are generally non-specific. Eclampsia is present when grand mal seizures occur (51).

Hepatic involvement can present with epigastric or right upper quadrant pain, likely from hepatomegaly stretching Glisson's capsule. Liver injury results as a consequence of vasoconstriction and fibrin precipitation in the liver. AST and ALT elevations can be striking. Complications can include hematoma below Glisson's capsule and hepatic rupture (52).

The magnitude of the liver chemistry abnormalities parallels the risk of adverse maternal but not fetal outcomes. Liver tests cannot exclusively be used to gauge clinical decisions, as the presence of normal liver enzymes does not exclude disease (53,54). An expectant approach is advised until after 34 weeks gestation to limit fetal morbidity (55). However, delivery is the only curative treatment and after 36–37 weeks there is no advantage in continuing the pregnancy (56).

**HELLP syndrome.** The HELLP syndrome is characterized by hemolytic anemia, increased liver enzymes, and low platelets. HELLP affects a minority of pregnancies but complicates up to 20% of cases of severe preeclampsia/eclampsia. Although HELLP typically presents between 28 and 36 weeks of gestation, 30% manifest symptoms in the first week postpartum (57). Risk factors include advanced maternal age, nulliparous, and multiparity (58).

The hypertension-related liver diseases share similar clinical presentations. Differentiation is difficult as there is overlap in their features. The diagnosis of HELLP is most often made through recognition of typical laboratory results. Signs of hemolytic anemia and thrombocytopenia with platelets <100,000 cells/μl, elevations in AST, ALT, serum bilirubin, and lactate dehydrogenase are expected (57). There are no pathognomonic clinical signs and some women with HELLP may be asymptomatic. Right upper quadrant and epigastric pain, nausea, vomiting, malaise, headache, edema, and weight gain are common complaints. Hepatomegaly and proteinuria should be expected, occurring in up to 80% of cases. Jaundice is rare, occurring in only 5% of patients.

Maternal consequences can be severe with mortality rates of 1–3% (59,60). Progression can also be rapid but laboratory values typically begin to normalize 48h postpartum (60). Fetal prognosis is most strongly linked to gestational age at delivery and birth weight.

Hepatic consequences include hepatic infarction, subcapsular hematomas, and intraparenchymal hemorrhage. When the ALT or AST is >1,000 U/l or abdominal pain radiates into the right shoulder, cross-sectional imaging can assist in excluding hepatic complications with more accuracy than ultrasound. Hepatic infarction should be suspected with right upper quadrant pain with fever, whereas abdominal swelling or shock presentation can occur with hepatic rupture (61,62). Supportive management is appropriate for most contained hematomas. Surgery is indicated for those with enlarging hematomas or evidence of rupture with hemodynamic instability. Alternatively, successful percutaneous embolization of the hepatic arteries in stable women has been reported (63). Liver transplantation has also been an effective salvage in patients with continued decompensation despite standard interventions (64).

Glucocorticoids are often part of the therapeutic protocol in HELLP, especially in pregnancies <34 weeks where they accelerate pulmonary maturity during expectant management. The University of Mississippi developed a treatment protocol that is often applied as a combination therapy in the management of women with HELLP. Known as “The Mississippi Protocol”, it includes corticosteroids, magnesium sulfate, and systolic blood pressure control (65).

Ear recognition, prompt delivery, and supportive care are essential to optimize maternal and fetal prognosis, as the postpartum clinical course is dependent on the interval between symptoms and termination of the pregnancy (69). If hepatic function does not rapidly improve, evaluation for liver transplantation offers the patient the best chance for survival (69,70).

Presenting symptoms are non-specific: nausea, vomiting, and abdominal pain. Concomitant preeclampsia is present in roughly one half of the affected women (71). Striking aminotransferase elevations and hyperbilirubinemia are typical. Hepatic failure can manifest with signs of hepatic dysfunction such as encephalopathy, coagulopathy, and hypoglycemia. Renal dysfunction and pancreatitis are common (72).

The diagnosis of AFLP is usually made clinically based on compatible presentation, laboratory, and imaging results. The “Swanse A Criteria” (Table 4) combine symptoms and laboratory derangements (73). These criteria have been validated in a large cohort in the United Kingdom, where the incidence of AFLP was 5.0 cases per 100,000 maternities. The “Swanse A Criteria” had substantial agreement with the clinical diagnosis of AFLP. Although there was only 1 death in this series, 65% were admitted to an intensive care or specialty liver unit (69). When the Swanse A Criteria were applied to a large group of women with suspected pregnancy-related liver disease who underwent liver biopsy, the screening tool offered an 85% positive predictive value and 100% negative predictive value for hepatic microvesicular steatosis. The authors felt confident that the Swanse A Criteria could obviate the need for liver biopsy in clinical management (74).
Pregnant women presenting with acute hepatitis should be tested for common etiologies of acute liver injury including viral hepatitis, hepatitis A virus (HAV), hepatitis B virus (HBV), hepatitis E virus (HEV), and herpes simplex virus (HSV; strong recommendation, very low level of evidence).

There are no published systematic reviews or meta-analysis on the evaluation and management of hepatitis A, hepatitis E, or HSV hepatitis during pregnancy.

Although acute infection with HAV has been associated with preterm labor and premature rupture of membranes, this has been reported to have no significant impact on maternal or fetal outcomes (79). The pregnant state does not appear to alter the course of acute HAV infection. Nevertheless, pregnant women presenting with acute hepatitis should be tested for HAV-IgM as vertical transmission of HAV has been reported, even leading to outbreaks within neonatal care units (80,81). In addition to careful infection control precautions, the CDC recommends HAV immunoglobulin treatment for the neonate if the maternal HAV infection occurs within 2 weeks of delivery (82). Treatment is otherwise supportive.

HEV infection has achieved notoriety with its association with pregnancy and reports of increased risk of acute liver failure leading to high maternal and infant mortality in Southeast Asia (83,84). Reports of acute HEV are rare in the United States and Europe although it may be under-diagnosed owing to limited awareness regarding HEV (85,86). However, pregnant women presenting with acute hepatitis should be tested for HEV with HEV-IgM to make the diagnosis and to increase anticipation and preparation for possible progression to acute liver failure and need for liver transplantation evaluation. Treatment is otherwise supportive.

Although hepatitis from HSV is very rare, HSV seroprevalence is common in women of child-bearing age in the United States at ~20% for HSV-2 and 60% for HSV-1 (87). Clinical clues to HSV hepatitis are the presence of fever, upper respiratory infection symptoms, or an anicteric, severe hepatitis presentation on laboratory testing. The pathognomonic mucocutaneous lesions are present in <50% of cases, requiring a high index of suspicion for HSV in the pregnant patient with an acute hepatitis presentation. The challenge of HSV hepatitis is that the diagnosis is difficult to make and has extremely high mortality rates reported up to 74% (88). This diagnostic difficulty is compounded by limited specificity and sensitivity of routine HSV-IgM testing. HSV PCR should be performed when HSV hepatitis is suspected (89,90).

Empiric acyclovir is recommended if HSV hepatitis is suspected in a pregnant patient. Acyclovir is already recommended by the American College of Obstetrics and Gynecology as prophylaxis at 36 weeks of pregnancy to prevent HSV recurrence and vertical transmission in women with previous infection with HSV (91). Acyclovir should be started once HSV hepatitis is suspected, as the diagnosis is difficult to make and often delayed and as acyclovir has been shown to be safe and well-tolerated in pregnancy (92–94). As HSV hepatitis is associated with poor outcomes, even with appropriate acyclovir treatment initiation and availability of liver transplantation, there is little to lose in initiating acyclovir once HSV hepatitis is suspected as early treatment is associated with improvement in outcomes (89,95). On the other hand, empiric acyclovir is not recommended in all pregnant patients with hepatitis when

HSV infection is not suspected (96). The key is to have a low threshold to suspect HSV hepatitis, especially if the pregnant patient has a fever, anicteric severe hepatitis on laboratory testing, and a rash. Acyclovir can then be discontinued if the HSV PCR is negative.

Acute HBV infection or reactivation of HBV can present during pregnancy and it may be difficult to differentiate reactivation from acute HBV infection. Nevertheless, HBV testing with HBsAg and hepatitis B core IgM is recommended in pregnant patients presenting with acute hepatitis. Management of HBV during pregnancy is covered elsewhere in this guideline.

CHRONIC LIVER DISEASES, CIRRHOSIS, AND LIVER TRANSPLANTATION

Recommendations:

Hepatitis B.

22. Active–passive immunoprophylaxis with hepatitis B immune globulin and the HBV vaccination series should be administered to all infants born to HBV-infected mothers to prevent perinatal transmission (strong recommendation, low level of evidence).

23. Women chronically infected with HBV and high viral load (>200,000 U/ml or >10⁹ log copies/ml and higher) should be offered antiviral medication with tenofovir or telbivudine in the third trimester to reduce perinatal transmission of HBV (strong recommendation, low level of evidence).

24. C-section should not be performed electively in HBV-positive mothers to prevent fetal infection (strong recommendation, very low level of evidence).

25. Women chronically infected with HBV should be allowed to breastfeed as recommended for infant health (strong recommendation, very low level of evidence).

Chronic HBV infection is estimated to affect >350 million people worldwide and represents a significant source of morbidity and mortality related to cirrhosis and hepatocellular carcinoma. Mother-to-child transmission (MTCT) of HBV remains an important source of incident cases of HBV. Current barriers to eradication of incident HBV infections via MTCT include underutilization of immunoprophylaxis with hepatitis B vaccination and hepatitis B immunoglobulin in certain endemic regions as well as failure of immunoprophylaxis.

The risk for development of chronic HBV infection is strongly linked to the age of exposure. Risk for chronic infection after exposure varies from ~90% in infants, 50% in toddlers and young children, and 5% in adults (97). MTCT rates also vary significantly according to the mother’s HBeAg status (70–90% transmission rate for HBeAg+ mothers vs. 10–40% for HBeAg-mothers). Standard active–passive immunoprophylaxis with HBlG and hepatitis B vaccination administered immediately after birth (within 12 h) to infants of HBsAg-positive mothers, followed by 2 additional doses of vaccine within 6–12 months, prevents transmission in ~95%. However, recent review of published literature from 1975 to 2011 demonstrated that active–passive immunoprophylaxis fails to prevent HBV transmission in 8–30% of children born to highly viremic mothers (98). Postulated causes of immunoprophylaxis failure include high levels of maternal viremia, intrauterine infection, or mutations of the HBV surface protein (99,100). Thus a clinical need remains to identify all causes of immunoprophylaxis failure and to determine safe and effective means of reducing MTCT rates.

High maternal viremia is correlated with the highest risk for the transmission of HBV in pregnancy. In a large, nested case-control study of 773 HBsAg-positive women in Taiwan, high levels of HBV DNA (≥1.4 ng/ml or ~3.8×10⁶ copies/ml) in HBeAg-positive women was associated with an odds ratio of 147 for chronic infection in infants (101). Even in the era of immunoprophylaxis, viremia remains a strong predictor of MTCT. In a study of 138 babies born to HBsAg-positive women, Wiseman et al. (102) found the immunoprophylaxis failure rate to be 9%, all occurring with mothers who were HBeAg-positive with HBV DNA ≥8 log₁₀ copies/ml (2×10⁷ U/ml). Recent literature also provides useful data to risk stratify the magnitude of MTCT risk and immunoprophylaxis failure according to varying thresholds of maternal HBV DNA. These data suggest that HBV DNA levels of 6–6.99 log₁₀ copies/ml (2×10⁶ IU/ml to 1.9×10⁷ IU/ml) portends a 3% risk of transmission, 7–7.99 log₁₀ copies/ml (2×10⁷ IU/ml to 1.9×10⁸ IU/ml) a 7% risk of transmission, and >8 log₁₀ copies/ml (2×10⁸ IU/ml) in the mother portend an 8% risk of MTCT of HBV (103).

Older data assessing MTCT rate in infants born via cesarean section vs. vaginal delivery failed to conclusively show a significant difference in neonatal HBV infection. Expert opinion has suggested that there were insufficient data to recommend changes in the mode of delivery for HBV-infected women (104,105). Some more recent data support reconsideration of elective cesarean section to reduce MTCT including a meta-analysis that suggested a 17.5% absolute risk reduction compared with immunoprophylaxis alone. However, other studies report no benefit to elective cesarean section (106). Data from Beijing of 1,409 infants born to HBsAg-positive mothers from 2007 to 2011, all of whom received appropriate immunoprophylaxis at birth, reported MTCT rates of 1.4% with elective cesarean section compared with 3.4% with vaginal delivery and 4.2% with urgent cesarean section (P<0.05) (107). When mothers in this study were stratified according to HBV DNA, in those with low HBV DNA (<1,000,000 copies/ml or 2×10⁸ IU/ml), delivery modality did not impact MTCT. This suggests a potential role for elective cesarean section among women with HBV DNA >1,000,000 copies/ml (2×10⁸ IU/ml). However, before definitive recommendations can be made, validation studies are needed to determine the relative safety and efficacy of elective cesarean section and immunoprophylaxis vs. immunoprophylaxis alone in reducing MTCT without compromising fetal outcomes (107,108).

There is a growing body of literature to support both the safety and efficacy of antiviral therapy initiated in late pregnancy for reduction of MTCT among women in the highest risk
for immunoprophylaxis failure (those with HBV DNA levels in the range of $10^7$ log copies/ml and higher). Han conducted a prospective, open-label trial of women aged 20–40 years who were HBeAg+ with HBV DNA>$7$ log$_{10}$ copies/ml ($2\times10^6$ IU/ml) between gestation week 20–32. All women were offered antiviral therapy and 135 who accepted received telbivudine 600 mg daily. The comparison arm consisted of 94 women who consented to participate in the trial but declined antiviral therapy. All infants were administered appropriate immunoprophylaxis. Mean viral load at enrollment was $-8$ log$_{10}$ copies/ml ($2\times10^7$ IU/ml) in both arms and was reduced to $2.44$ log$_{10}$ copies/ml in the telbivudine-treated arm before delivery. The reported MTCT rate was 0% with telbivudine therapy compared with 8% without antiviral therapy. One infant in each group had LBW and there were 6 with telbivudine therapy compared with 8% without antiviral therapy at any point during or after pregnancy requires careful monitoring because of the potential for HBV flares upon antiviral therapy withdrawal.

Transmission of HBV with breastfeeding is low risk in infants who receive appropriate immunoprophylaxis. Current WHO recommendations are to allow breastfeeding as there is no evidence for additional risk, even without immunization. (Protection against viral hepatitis, Recommendations of Immunization Practices Advisory Committee (ACIP), MMWR 1990;39(no S-2) WHO Update No 22, Nov 1996) Breastfeeding should be avoided in the presence of breast pathology such as cracked or bleeding nipples. Oral nucleos(t)ide analogs have been shown to be excreted in breast milk, albeit at low levels, and there is limited data on the effect of these medications on infants (111).

**Hepatitis C (HCV)**

26. All pregnant women with risk factors for HCV should be screened with anti-HCV antibody. Screening should not be performed in women without risk factors for HCV acquisition (strong recommendation, low level of evidence).

27. Invasive procedures (e.g., amniocentesis, invasive fetal monitoring) should be minimized in infected mothers and their fetus to prevent vertical transmission of hepatitis C (strong recommendation, very low level of evidence).

28. C-section should not be performed electively in HCV-positive mothers to prevent fetal infection (strong recommendation, very low level of evidence).

29. Women chronically infected with HCV should be allowed to breastfeed as indicated for infant health (strong recommendation, very low level of evidence).

30. Hepatitis C therapy should not be offered to pregnant women to either treat HCV or decrease the risk for vertical transmission (strong recommendation, very low level of evidence).

Chronic infection with the HCV can lead to significant liver-related morbidity and increases in all-cause mortality. Conservatively, >3 million Americans are estimated to be chronically infected with HCV, with 75% born between 1945–1965. Prevalence is generally low in the prenatal population (112).

HCV has little impact during pregnancy with minimal risk to either the mother or infant. However, there may be a higher risk for premature rupture of membranes and gestational diabetes in women with HCV (113,114). ALT and viral loads fluctuate but these changes lack clinical significance. Pregnancy induces a state of relative immune suppression followed by immune reconstitution postpartum. The changes in liver enzymes and viral kinetics mirror a response to this immune modulation. During the second and third trimester aminotransferase levels decline, only to rebound postpartum. Viral load also fluctuates, peaking during the third trimester then returning to pre-pregnancy levels after delivery (115,116). Unlike HBV, postpartum flares of HCV have not been described.

Although HCV is transmitted through percutaneous exposure of infected blood or body fluids, screening for HCV is not part of routine perinatal testing owing to a combination of low rates of perinatal transmission and low prevalence of HCV in pregnant women. Cross-sectional studies estimate that only 0.5–8% of pregnant women have anti-HCV (117,118). As in the general population, the prevalence of anti-HCV is higher in those who engage in risk factors that increase potential exposure. Pregnant women should be screened using the same guidelines as the general population (119,120).
Although there is only a 3–10% risk of transmitting HCV at the time of birth, vertical transmission remains responsible for the majority of childhood HCV infection. This risk is highest in pregnant women co-infected with HIV. Unfortunately, there is no perinatal management strategy that can clearly decrease this risk. Although studies have reported conflicting findings, it is generally recommended that invasive procedures, such as internal fetal monitoring devices, should be avoided (121).

Although prolonged (>6 h) rupture of membranes may increase the risk of transmission, vaginal delivery itself does not appear to increase the risk of vertical transmission of HCV transmission compared with cesarean delivery (121,122).

There is no evidence of an association between breastfeeding and risk for vertical transmission (121). Still, breastfeeding should be avoided when the potential risk for exposure is higher, such as when there are cracked nipples or skin breakdown.

HCV can be eradicated effectively with either all-oral- or interferon-based treatment options. HCV rarely requires urgent therapy, making it easier to defer treatment decisions until after delivery. In addition, both interferon and ribavirin are strictly contraindicated during pregnancy. There is no data at this time to guide or support the use of all-oral combination therapy during pregnancy.

Autoimmune hepatitis

31. Pregnant women with autoimmune hepatitis (AIH) should be continued on their treatment with corticosteroids and/or azathioprine (AZA) (strong recommendation, very low level of evidence).

32. Pregnant women with primary biliary cirrhosis (PBC) should be continued on their treatment with UDCA (strong recommendation, very low level of evidence).

33. Pregnant women with Wilson’s disease (WD) should be continued, with dose reduction if possible, on their treatment with penicillamine, trientine, or zinc (strong recommendation, very low level of evidence).

34. Pregnant women with suspected portal hypertension should undergo screening with upper endoscopy for esophageal varices in the second trimester (strong recommendation, low level of evidence).

35. Pregnant women who are found to have large esophageal varices should be treated with beta-blockers and/or band ligation (conditional recommendation, very low level of evidence).

36. Pregnant women with a history of liver transplantation should continue their immunosuppression except for mycophenolic acid (strong recommendation, moderate level of evidence).

There are no published systematic reviews or meta-analysis on the management of AIH, PBC, or WD during pregnancy although there are several systematic reviews on treatment for these diseases in general.

The key for successful pregnancy outcomes in women with chronic liver disease appears to be appropriate counseling regarding fertility and optimal management of the liver disease before, during, and after the pregnancy. The most challenging issue in this setting is the management of medications used for the treatment of the underlying chronic liver disease with regard to dosing, effectiveness, and safety. Limiting the discussion is the paucity of data on specific medications in the setting of liver disease and pregnancy. Nevertheless, a principle that becomes evident in reviewing the intersection of medical therapy, chronic liver disease, and pregnancy is that a healthy mother has the best chance to have a healthy baby and optimal maternal outcomes. Thus, in women with chronic liver diseases, such as AIH, PBC, or WD, contemplating pregnancy, optimal control of the chronic liver disease is advised. The risks of not treating the liver disease in the pregnant state with subsequent risk to maternal and fetal health outcomes must be considered in addition to the benefits and risks of the treatment regimens.

It is difficult to discriminate between the potential impact of underlying maternal liver diseases and therapies for these diseases, on the risks of maternal or fetal complications.

Moreover, because adverse events such as congenital malformations are very rare, available data are limited to case reports and case series. The limited data on the effectiveness and safety of therapies for these liver diseases during pregnancy has often led to dependence on extrapolated data from use of these therapies during pregnancy in other disease processes in pregnancy such as inflammatory bowel disease, autoimmune diseases, or organ transplantation. The limitations of such extrapolations must be acknowledged, and caution taken in generalizing these conclusions to patients with liver disease.

AIH is associated with an increased risk of fetal prematurity and loss, with worse outcomes with inadequate AIH activity control, especially in the absence of or discontinuation of AIH treatment before or during pregnancy (123). Although AIH was historically thought to be quiescent during pregnancy, more recent data suggest that AIH may have an initial presentation during pregnancy, an intrapartum flare risk of >20% and postpartum flare risk of up to 30–50% (124,125). Treatment for AIH is based on immunosuppression with corticosteroids and/or AZA, with recent practice guidelines for AIH recommending prednisone monotherapy for pregnant individuals (126). A systematic review of AIH treatment concluded that corticosteroids +AZA was appropriate for induction whereas corticosteroids ±AZA or AZA monotherapy was superior to corticosteroid monotherapy for maintenance management of AIH (127). However, there are no systematic reviews or meta-analysis on the treatment of AIH during pregnancy. In the absence of such data, it is important to consider that flares of AIH during pregnancy may be potentially more detrimental to neonatal outcomes than the potential risk of medical therapy needed to control and prevent AIH flares.

Corticosteroids, pregnancy category C drugs, have been studied in a population-based study of >51,000 corticosteroid-exposed
pregnancies, with no increase in orofacial cleft defects or other significant adverse events (127). Corticosteroid monotherapy has traditionally been used for the management of AIH flares during pregnancy because AZA is a pregnancy category D drug, which has limited its use (127). Concerns regarding AZA arose from animal studies using suprapharmacologic doses and non-oral delivery routes such as intraperitoneal or subcutaneous dosing, associated with limbic malformations, cleft palate, skeletal anomalies, and hematopoietic suppression. However, utilization of AZA during pregnancy for treatment of AIH has been reported to be safe in a limited number of case reports and series (128–136). AZA treatment in AIH during pregnancy has not been studied systematically. However, utilization of AZA during pregnancy has been studied systematically in inflammatory bowel disease with 3,000 AZA-exposed pregnancies showing an association with preterm births but no increase in congenital abnormalities or LBWs (137). Studies of AZA in other autoimmune diseases and inflammatory bowel disease have found scattered reports of preterm births but no increased risk of congenital abnormalities, spontaneous abortions, or infections supporting the growing evidence regarding the acceptability of AZA during pregnancy (138–142). The mounting evidence of AZA’s safety during pregnancy coupled with the importance of achieving and maintaining AIH disease control during pregnancy supports the mandate that treatment continuation for AIH is critical in optimizing maternal and fetal outcomes. The potential benefit of treatment with corticosteroids and AZA to keep the mother’s AIH in control appears to be significantly greater than the potentially small risk of treatment-associated adverse events on the mother and fetus.

**Primary biliary cirrhosis.** Older literature suggested poor outcomes of pregnancy in patients with PBC (143). As patients with PBC tend to present at an older age after the usual child-bearing age, and as women with PBC were discouraged in the past from pursuing pregnancy, there is an extremely limited number of studies on PBC and pregnancy. However, more recent studies have reported good maternal and fetal outcomes (144). PBC has been associated with disease flare after delivery (144,145). UDCA is a pregnancy category B drug that is generally recommended for PBC (146). Studies on the use of UDCA treatment for PBC during pregnancy have been limited, especially in the first trimester (147,148). Similar to the situation with AIH, the potential risks of UDCA during pregnancy appear small compared with the potential positive effect of treatment on maternal and fetal outcomes. With growing evidence that UDCA is safe during pregnancy in other diseases such as intrahepatic cholestasis of pregnancy, and the unlikely scenario that large-scale studies will be performed on the efficacy and safety of UDCA during pregnancy for PBC, it appears prudent to recommend continuation of UDCA for PBC during pregnancy at this time (149,150).

**Wilson’s disease.** WD is postulated to lead to reduced fertility as copper deposition in the uterus may interfere with embryo implantation leading to an increase in miscarriages and spontaneous abortions (151). WD and the complex nature of its management would benefit from referral to high-risk pregnancy multidisciplinary specialists in maternal–fetal medicine and liver disease. Pregnancy in general does not appear to change the course of WD progression (152). However, treatment discontinuation or a lack of treatment has been reported to lead to disease flares with attendant risk of hepatic decompensation or liver failure (153). There is one recent systematic review on the treatment of WD in general, but no reports specific to treatment for WD during pregnancy (154). Similar to AIH and PBC, the decision regarding treatment for WD must weigh the potential risks and adverse effects of treatment vs. not only the benefits of treatment but the risks of not treating the WD during pregnancy. Practice guidelines for WD recommends continuing treatment during pregnancy, but reducing penicillamine or trientine doses by 25–50% to promote wound healing in the event that a cesarean section is needed (155). There is inadequate data to make recommendations on a preferred treatment for WD during pregnancy, between penicillamine, trientine, or zinc. Some data on conversion to zinc therapy during pregnancy has also been reported (156–158). There are also multiple case reports of fetal myelosuppression or embryopathy associated with penicillamine treatment during pregnancy for WD (159–162). On the other hand, treatment discontinuation or lack of treatment for WD can not only lead to maternal hepatic decompensation but can also lead to copper deposition in the placenta and fetal liver, damaging the fetus along with recognized risks of maternal hepatic decompensation. The risks of treatment discontinuation or lack of treatment for WD during pregnancy appears to outweigh the potential risks of treatment. The data to recommend dose reduction of penicillamine in anticipation of possible cesarean section appears to be very limited.

**Cirrhosis and portal hypertension.** There are no published systematic reviews or meta-analyses on the management of cirrhosis or portal hypertension during pregnancy, likely because of the low prevalence of cirrhosis in women of reproductive age and reduced fertility of women with cirrhosis. Appropriate discussion regarding pregnancy and counseling regarding the management of cirrhosis during pregnancy is critical for optimizing outcomes. Pregnant women with cirrhosis should ideally be managed in a multidisciplinary setting with maternal–fetal medicine along with gastroenterology/hepatology (163). Similar to the management of chronic liver disease in pregnancy, the principle of optimizing the management of cirrhosis and portal hypertension appears prudent to enhance maternal and fetal outcomes.

Pregnancy in women with underlying cirrhosis has been associated with an increase in prematurity, spontaneous abortions, and maternal–fetal mortality (164–166). Non-cirrhotic portal hypertension has been reported to have better outcomes than cirrhotics with portal hypertension (167). Variceal bleeding is the most frequent and feared complication of portal hypertension during pregnancy, with an increased risk at delivery and...
Liver transplantation. Fertility is rapidly restored after successful liver transplantation, with reports of 80% normalization of the menstrual cycle within 1 year and as early as a few months after liver transplantation (179). Most experts advocate waiting at least 1 year, and some up to 2 years after liver transplantation before planning a pregnancy, citing the lower doses of immunosuppression use, lower risk of acute cellular rejection, and lower risk of opportunistic infections after the first year of liver transplantation (180). The key is to initiate timely and appropriate discussions with the patient regarding fertility and pregnancy possibilities, with the goal of planned management with maternal–fetal medicine providers and the liver transplant center.

There is one published systematic review on pregnancy outcomes in liver transplant recipients (181). Higher rates of preterm births and cesarean sections compared with the general population were reported. The National Transplantation Pregnancy Registry, a questionnaire-based registry, has reported a higher risk of prematurity, LBW, maternal hypertension and preeclampsia, and cesarean sections compared with the general population (182). Higher risk of acute cellular rejection and graft loss were noted if pregnancy occurred within 6 months of liver transplantation. Overall, the literature suggests that pregnancy in liver transplant recipients is safe and not uncommon, with good outcomes given careful management and monitoring (183–184). The key is to maintain liver graft function to support the mother’s health to maximize the opportunity for a healthy pregnancy and delivery of a healthy baby (185).

There is one meta-analysis on pregnancy and cyclosporine in transplant recipients (186). There are no other meta-analyses or systematic reviews on pregnancy and use of tacrolimus, AZA, mycophenolic acid, sirolimus, everolimus, or corticosteroids in the setting of liver transplantation. It should be noted that reports of maternal and fetal outcomes, and potential adverse events while on these immunosuppressive medications may be confounded by the underlying disease activity, concomitant medical comorbidities, other medications being utilized, as well as the pregnancy state itself in the post-liver transplant setting. Overall, with the exception of mycophenolic acid, the risks of cyclosporine, tacrolimus, AZA, sirolimus, everolimus, and corticosteroids appear low compared with the risks of acute cellular rejection or graft loss with their discontinuation or attenuation. Although a higher risk of prematurity and LBW have been reported, the risks of congenital malformation do not appear to be significantly higher than the risk in the general population, without a specific pattern of malformation identified (187–192). Compared with tacrolimus and cyclosporine, there is less data on the use of everolimus and sirolimus during pregnancy after liver transplantation, with more of the data available for kidney transplant recipients. The potential for impaired wound healing with everolimus and sirolimus must be considered if cesarean section is performed (193–196). It is clear that mycophenolic acid should not be used during pregnancy owing to risk of congenital malformations and embryo-fetal toxicity (197–200).

Expert and society recommendations have traditionally opposed breastfeeding in the setting of immunosuppression medications and transplantation, given the potential for harm of these medications and a lack of safety data (201). More recently, small series have reported safety with minimal to no adverse events for babies.
who are breastfed while mothers are on immunosuppression medications after liver transplantation (202–205). In addition, pharmacokinetic and drug safety data on breast milk concentrations have suggested minimal excretion of these immunosuppressants into breast milk (206–208). The accumulation of these data, albeit still limited, in addition to the growing recognition of the importance of breastfeeding, has led to a push to loosen these traditional dictums against breastfeeding, especially if the mother is interested in breastfeeding her baby.

CONCLUSION
Clinical evaluation of the pregnant woman who presents with liver test abnormalities relies on the accurate determination of intrinsic liver disease or liver disease related specific to pregnancy. Judicious and timely evidence-based management most often results in good maternal and fetal outcomes.
